Tufted Puffins as Samplers of Forage Fish

Restoration Project (APEX) 95163D
Final Report

Study History: Restoration Project 95163D was initiated as part of the Alaska Predator Ecosystem Experiment (APEX) project to study seabird and forage fish interactions in Prince William Sound. Puffins have been used historically as samplers of marine fish communities in the Gulf of Alaska because they typically catch and deliver whole, fresh samples of forage fish to their offspring. These samples are relatively simple to collect at colonies. In addition, parameters of breeding, such as meal delivery rates, chick growth rates, and reproductive success, can be used to infer information about the abundance and availability of local prey stocks. In summer 1995, Tufted Puffins were used as ‘samplers’ to assess prey availability to other seabirds in Prince William Sound that were affected by the spill, but whose populations have not recovered from losses incurred during the spill.

This pilot project was not continued after 1995 for several reasons: i) We found that the diets of Tufted Puffins (mostly pollock, salmonids, and prowfish) were quite different from the diets of those seabirds (kittiwakes, Pigeon Guillemots) of primary concern to the EVOS Trustees. In 1995 (and other years), Black-legged Kittiwakes fed mostly on herring and sand lance, and Pigeon Guillemots ate primarily benthic fish (pricklebacks, eelblennies) and sand lance; ii) Hydroacoustic and mid-water trawl surveys conducted by other APEX investigators were very successful in determining the abundance and distribution of forage fish in offshore areas used by Tufted Puffins, and so sampling by puffins was redundant; iii) Owing to logistic constraints and small puffin colonies, we were not able to obtain very large samples of forage fish from puffins, and thus sampling was not particularly cost-effective (especially compared to trawling); and, iv) Most of the prey used by kittiwakes and guillemots occurred close to shore and not in the areas sampled by puffins. While trawl sampling effort could be shifted to inshore areas, puffin sampling could not. In summary, a decision was made to terminate Restoration Project 95163D because puffins were not providing adequate sample sizes of forage fish, nor sampling appropriate species of prey in relevant areas of Prince William Sound.

Abstract: Habitat use, diet and breeding biology of Tufted Puffins (Fratercula cirrhata) were studied in Prince William Sound during summer 1995. On Seal Island, 112 puffin burrows (71.4% active) were located. Of 95 accessible burrows, 49.5% were typical earthen burrows, whereas the remainder were atypical for the species (e.g., under tree roots). Hatching success (≤79%), fledging success (≥82%), chick growth rates (17.7 g/d), asymptotic (600 g) and fledging (563 g) weights, meal sizes (14.2 g), meal delivery rates (5.32 meals/d), and daily rations (75.5 g/d) were all average or above-average for Tufted Puffins in Alaska. A total of 42 chick meals, comprising 125 individual prey, was collected. Meals were comprised of juvenile pollock (12.7% of total mass), herring (21.8%), prowfish (32.3%), salmonids (24.1%), and capelin, sand lance and squid (<5% each). We conclude that Tufted Puffin populations in Prince William Sound are relatively small, and may be limited by low densities of prey in the Sound, nest-site availability, and heavy rainfall.

Abstract-- Habitat use, diet and breeding biology of Tufted Puffins (*Fratercula cirrhata*) were studied in Prince William Sound, Alaska, during summer 1995. On Seal Island, 112 puffin burrows (71.4% active) were located. Of 95 accessible burrows, 49.5% were typical earthen burrows, whereas the remainder were atypical for the species (e.g., under tree roots). Hatching success (≥79%), fledging success (≥82%), chick growth rates (17.7 g/d), asymptotic (600 g) and fledging (563 g) weights, meal sizes (14.2 g), meal delivery rates (5.32 meals/d), and daily rations (75.5 g/d) were all average or above-average for Tufted Puffins in Alaska. A total of 42 chick meals, comprising 125 individual prey were collected. Meals were comprised of juvenile pollock (12.7% of total mass), herring (21.8%), prowfish (32.3%), salmonids (24.1%), and capelin, sandlance and squid (<5% each). Tufted Puffin populations in Prince William Sound are relatively small, and may be limited by low densities of prey in the Sound, nest-site availability, and heavy rainfall.

Key words: Tufted Puffin, forage fish, diet, reproduction, growth rate, breeding habitat, Prince William Sound, *Exxon Valdez*
Tufted Puffins (*Fratercula cirrhata*) are widely distributed throughout the North Pacific, with breeding colonies in North America that range from California to the Arctic Ocean (Byrd et al. 1993). Although 45% of this population of 2.7 million birds is concentrated in the Gulf of Alaska, relatively few puffins breed in Prince William Sound despite having numerous islands that are available for nesting. Colony censuses and boat-based surveys suggest that only about 5,000 Tufted Puffins breed in Prince William Sound during summer (Sowls et al. 1978, Klosiewski and Laing 1994).

Tufted Puffins breed mostly on treeless islands and prefer to nest near the tops of steep maritime slopes (Vermeer 1979). Most Tufted Puffins make their nests by burrowing deep into soft peat or sod substrate, although they regularly make use of rock crevices on cliff faces or talus slopes. In contrast, closely-related Rhinoceros Auklets (*Cerorhinca monocerata*) nest extensively on islands with trees, often burrowing under the roots of trees adjacent to cliff-edges (Vermeer 1979). Such behavior has not been reported for Tufted Puffins.

Tufted Puffins are flexible in their choice of prey and consume a wide variety of forage species throughout their range (Vermeer 1979, Wehle 1983, Hatch and Sanger 1992). In the northern Gulf of Alaska, Tufted Puffins eat small to mid-sized forage fish, including sandlance (*Ammodytes hexapterus*), capelin (*Mallotus villosus*), herring (*Clupea harengus*), juvenile walleye pollock (*Theragra chalcogramma*) and Pacific cod (*Gadus pacifica*). Availability of high quality prey within reasonable foraging distance of colonies is required to sustain chick production and healthy populations.

When the T/V Exxon Valdez spilled more than 43 million liters of crude oil into Prince William Sound and the Gulf of Alaska in 1989, it appeared that few Tufted Puffins were killed outright by exposure to oil (Piatt et. al. 1990). However, effects of the spill on seabird populations by direct mortality or indirectly through effects on prey availability have been difficult to assess because of poor baseline data and natural background variability (Piatt and Anderson 1996). For example, a marked change in diet has been observed for puffins and other seabirds in the Gulf of Alaska during the past two
decades. This change has been attributed tentatively to a large-scale shift in the Gulf of Alaska marine climate and associated changes in the availability of forage fish. These natural changes may have directly affected the population biology of piscivorous birds and mammals in the Gulf of Alaska (Piatt and Anderson 1996).

Our study was designed to gather basic information on the diet and biology of Tufted Puffins in Prince William Sound, and to assess indirectly the availability of local forage fish. It was part of a larger research project on seabirds and forage fish funded by the Exxon Valdez Oil Spill Trustee Council. Puffins are useful indicators of forage fish stocks because they eat what is locally available, and it is relatively easy to study their diets and breeding biology (Hatch and Sanger 1992). Other than population counts, almost no information on Tufted Puffins in Prince William Sound had been gathered prior to this study. We report here on the populations, diets, chick growth, breeding success, and nest-site selection by Tufted Puffins at Smith, Little Smith and Seal islands—the largest colonies for this species in Prince William Sound.

Study Area and Methods

From 24 June to 17 July, 1995, we observed seabirds at Smith (60° 31.2' N, 147° 21.6' W) and Little Smith (60° 31.2' N, 147° 25.2' W) islands in Prince William Sound, Alaska. Tufted Puffins were observed almost daily from an inflatable boat to determine where they were nesting. We conducted three surveys of both islands, counting all birds within 200 m of shore and all birds visible on land. Maximum numbers of other breeding seabirds at the islands included: 33 Pigeon Guillemots (Cepphus columba); 200 Marbled Murrelets (Brachyramphus marmoratus); 250 Parakeet Auklets (Cyclorrhynchus psittacula); 60 Horned Puffins (Fratercula corniculata); and 83 Glaucous-winged Gulls (Larus glaucescens). We were unable to find puffins nesting in accessible habitat on either island, and therefore we moved our camp 7 km south to Seal Island (60° 25.8' N, 147° 24.6' W).
Seal Island is a small, low-elevation, tree-covered island with rocky beaches around much of its perimeter. We could access most puffin breeding areas by walking around the island. We worked on Seal Island from 17 July until 8 September, 1995. We surveyed the island by boat to locate puffin breeding areas and census birds at sea, and we cut overland trails to breeding sites. We counted rafting and flying puffins opportunistically and recorded high counts for each day. Maximum numbers of other seabirds observed on Seal Island included: 40 Pigeon Guillemots; 10 Marbled Murrelets; 60 Parakeet Auklets; 6 Horned Puffins; 80 Glaucous-winged Gulls; and 600 Black-legged Kittiwakes (*Rissa tridactyla*).

Puffin nesting habitat on Seal island was divided into eight study plots based on general physiographic features. All plots, with the exception of one islet off the northeast shore, were located on the south half of the island. Within each plot we attempted to locate all occupied puffin burrows. Occupation was inferred when: i) a chick was found when the burrow was accessed; ii) a chick meal was found during screening of the burrow (see below); iii) an adult bird was observed delivering a meal to the burrow; iv) obvious signs of breeding activity were observed (excrement, eggshells or strong odor); or, v) a screen was removed by a bird from the entrance of the burrow.

Eleven Tufted Puffin chicks were measured throughout the chick-rearing period to obtain growth and development data. To gain access to these chicks, one or more holes were excavated in the soil, then plugged once the chick was returned to the burrow. Each burrow was visited once every 2-6 days and the following data collected: i) chick weight (±1g); ii) length of wing chord (±1mm); iii) length of exposed culmen (±0.1mm); and, iv) length of fifth and outer primary (±1mm). Maximum growth rates (g/d) were calculated for each of 10 chicks by measuring the slope of mass gained versus calendar date during the linear phase of growth (Gaston 1985).

To obtain nestling diet information, meal samples were collected using the burrow-screening technique (Hatch and Sanger 1992). Puffin burrow entrances were covered with a piece of fine-mesh hardware cloth to prevent adult birds from entering.
Adults delivering meals to chicks often drop prey at the burrow entrance when the screen is encountered. We screened 67 different burrows regularly, leaving the screens in place for 2-3 hr. Individual burrows were screened 1-9 times at intervals of 2-8 d. For safety, static lines and climbing harnesses were used to access almost all burrows.

Chick meals were collected and later identified to species (when possible), weighed (±0.1g) and measured (±0.1 mm). Subsamples were frozen for energetic analyses (D. Roby, in prep.), and some specimens were saved for later identification at the Univ. of Alaska, Fairbanks (K. Turco, Inst. Mar. Sci.). After sufficient subsamples of the major prey species had been obtained, we washed, weighed and measured fish samples at the burrow and returned the meal to the chick. No meals were collected from chicks that were used to assess growth rates.

To obtain data on chick provisioning rates, six Tufted Puffin burrows were monitored during 4 all-day watches on 28 July (16.5 hr), 11 August (16.0 hr), 20 August (15.5 hr) and 27 August (14.5 hr). Observations were made with binoculars from a blind, at a distance of 15-20 m from burrows. Information recorded during these watches included: i) the number of times an adult visited a particular burrow; and, ii) whether the bird delivered a meal.

Results

Numbers and Habitat Use

On 27 June we counted a maximum of 300 individual Tufted Puffins around Smith Island and 160 around Little Smith Island. Active colony sites on Smith Island were located on grassy and rocky slopes at the top of steep cliffs (100m elevation) on both sides of the east cape, and near the top of a steep escarpment (100-150m) along the north coast. These were the only areas where puffins were observed on land, and all sites were inaccessible to us. Puffins were concentrated on the east side of Little Smith, and some birds were observed landing near the top of steep cliffs (70-100m).
On 19 July we counted a maximum of 125 Tufted Puffins around Seal Island. We located 112 puffin burrows along 1.2 km of shoreline on the eastern and southern coasts. Burrows tended to be clumped in groups. Individual burrows were 0.5 to 10 m apart. Of the 112 burrows located, at least 80 (71.4%) were active in 1995. Of 95 burrows that we examined, 47 (49.5%) were typical earthen tunnels, 45 (47.4%) were associated with tree roots, and 3 (3.1%) were in rock crevices. Most nest-sites were located at the interface between forest and low-elevation cliff-tops above rocky beaches, wherever grassy turf was found.

Chick Growth and Development

Fourteen burrows were monitored to assess breeding success and obtain growth data from nestlings. Eleven of these burrows contained hatchlings during the first nest-check in late July, and 3 burrows contained eggs--2 of which never hatched and 1 from which the chick died upon hatching. Judging from chick development, we estimate mid-hatching occurred on about 20 July. Of the 11 chicks that were monitored, 9 (82%) had fledged by the time we left on 8 September. The remaining 2 chicks appeared ready to fledge (weights=485g and 685g) and probably did so successfully (Wehle 1983). Thus, maximum breeding success was about 79% (79% hatch, 100% fledge). We estimate that mid-fledging occurred on about 1 September.

Although there was considerable variation among chicks (Fig. 1), the maximum daily growth rate during the linear phase averaged 17.7 g/d (±2.8 s.d., n=10). For those chicks that could be measured throughout growth and to fledging (n=7), asymptotic mass was 600 g (±49 s.d.), fledging mass was 563 g (±53 s.d.), wing length at fledging was 143.3mm (±8.6 s.d.), and culmen length at fledging was 40.1mm (±1.6 s.d.).

Chick Meal Collections

A total of 42 chick meals was collected during the study. Of these, 35 were collected in 364 screening attempts (1072 nest-hours) for an overall screening success
rate of 9.6%. We opportunistically picked up an additional 7 meals where they had been dropped on the ground. Prey items were only collected from 31% of all puffin burrows that were screened (n=67). Most meals (43%) were collected upon the first screening of a burrow, and success declined markedly on subsequent attempts—suggesting that puffins learned to avoid dropping meals at screened burrow entrances. This effect has not been examined at other puffin colonies, where investigators have not collected meals from individually marked burrows (Hatch and Sanger 1992, J.F. Piatt, unpubl. data).

A total of 125 prey items was collected. The average weight of meal loads (n=35) was 14.2g (±15.9 s.d.), and on average, 3.2 prey items were delivered per load (range: 1-11). Juvenile walleye pollock and herring accounted for most (81.6%) of the fish delivered (Fig. 2), and occurred most frequently in individual meal loads (31% and 38%, respectively). However, in terms of biomass, juvenile prowfish (Zaprora silenus) and salmon (Onchorynchus spp.) were the dominant species (Fig. 2) because of their much larger masses (Table 1). Prowfish and salmon also occurred frequently in meal loads (17% and 10%, respectively). By number or mass, sand lance (n=3), capelin (n=1) and squid (Gonatidae, n=1) were minor components of the diet, although sand lance occurred in 7% of meal loads.

**Feeding Rates**

Tufted Puffins were active at their nest sites throughout the day (Fig. 3). Peak feeding activity occurred during the morning hours (before 0900 hr), and feedings generally tapered off through the day (Fig. 3). Adults were most active during the afternoon and late evening hours, however, as measured by the frequency of non-feeding entrances into the burrow (Fig. 3). Social behaviors (for example, resting at the colony, prospecting, bill gaping, billing and vocalizing; see Harris 1984) were observed more commonly in the afternoon and evening than in the morning.

In total, adults were observed entering the six study burrows 468 times during the four days of observation (see Methods), and on 103 of those visits they delivered food.
Daily feeding rates varied from a high of 7.0 meals/chick/d observed on 11 August, to a low of 3.0 meals/chick/d on 27 August. The latter rate is biased because puffins reduce the frequency of chick-feedings just prior to fledging of chicks (Harris 1984). The average feeding rate during the first three watches was 5.32 (±1.49) meals/chick/d, and reflects more accurately the average rate of feeding for most of the chick-rearing period. Thus, the average amount of food provided to Tufted Puffin chicks during the period of maximum food demand (ca. 25 July-25 August) was 75.5 g/d (delivery rate times average meal size).

Discussion

No other data on the biology of Tufted Puffins in Prince William Sound are available for interpretation. Compared to puffins elsewhere in Alaska and the Pacific Northwest, however, it appears that Tufted Puffins fared quite well at Seal Island in 1995 (Table 2). In terms of food delivery, chick growth and production, Seal Island puffins did as well or better than puffins at other major colonies in successful years (see references in Table 2).

In contrast to other studies (Table 2), the diet of Tufted Puffins at Seal Island was mostly prowfish and salmon, although pollock and herring were numerically dominant. In a wide-ranging study of Tufted Puffin diets in the Gulf of Alaska (Hatch and Sanger 1992), prowfish ranked 5th in importance (by weight), whereas salmon were generally very rare (ranking 30th). A small sample (n=2) of puffin chick meals from Naked Island, Prince William Sound in 1986 (Hatch and Sanger 1992) showed that diets there were comprised of salmon (76%) and pollock (24%).

Hydroacoustic and trawl surveys of forage fish populations in the immediate vicinity of Seal Island in 1995 (Haldorson et al. 1996) revealed that pollock (mostly 0+ age-class) were by far the most abundant (99% of trawl catches) forage fish in shallow and deep waters. Excluding pollock, capelin (44%), juvenile salmon (21%), prowfish
(5%), herring (3%) and sand lance (1%) were the commonest forage fish in the area. However, forage fish densities were generally low in Prince William Sound (e.g., 0.01-1 g/m²; Haldorson et al. 1996) compared to areas with large seabird populations (e.g., 0.1-10 g/m³ in lower Cook Inlet or Chukchi Sea; Piatt et al. 1990, J. Piatt, unpubl. data). Forage fish densities appeared adequate to support the small Tufted Puffin colonies that we observed, but may ultimately limit the expansion of populations in Prince William Sound. On the other hand, Tufted Puffins are opportunistic feeders and subsist successfully elsewhere in Alaska on a wide variety of prey types. Furthermore, Prince William Sound supports much larger populations of other piscivorous seabirds (e.g., murrelets and kittiwakes, Klosiewski and Laing 1994). In any case, one year of data is insufficient to test the hypothesis that food is limiting puffin populations.

If food is not limiting, the question arises: Why are there not more Tufted Puffins breeding in Prince William Sound? Puffins are notoriously difficult to census at colonies, and boat-based surveys have their own biases, but it appears that populations have remained relatively stable during the past 25 years. Boat surveys in 1973 suggest that Prince William Sound supported a Tufted Puffin population in summer of 4,439 ± 4,543 individuals (Klosiewski and Laing 1994). Similar surveys in 1991 suggested a population of 5,043 ± 2,011 individuals (Agler et al. 1994). In 1976 (Sowls et al. 1978), 554 and 166 Tufted Puffins were counted at Smith and Little Smith islands, respectively, while we counted a maximum of 300 and 160 Tufted Puffins, respectively, in 1995.

We can suggest two other reasons why Tufted Puffin populations may be limited in Prince William Sound. First, Tufted Puffins are primarily a burrow-nesting species, and the use of any breeding habitats other than steep, grassy maritime slopes is rare (Gill and Sanger 1979, Vermeer 1979). Tufted Puffins prefer to burrow in areas with sufficient soil depth, up to 1.5 m (Wehle 1980). On Seal Island, only half of nest-sites were typical earthen tunnels, whereas most of the remainder incorporated hollows under tree roots into their construction. While this is not unusual for Rhinoceros Auklets (Vermeer 1979), it has never been reported for Tufted Puffins. The nesting situation is similar on Naked
Island in Prince William Sound (J. Piatt, pers. obs.). Although Prince William Sound has many islands available for nesting, most are either completely forested, or, in northern glaciated areas, completely barren and free of soil. Thus, it seems likely that nest sites for Tufted Puffins are limited in Prince William Sound.

Secondly, as in Southeast Alaska and coastal British Columbia, it rains frequently in Prince William Sound during summer. On Seal Island, we recorded rain on 93% of days (n=14) in July (total 8.0 cm) and on 42% of days in August (10.9 cm). Long-term (1950's to 1990's; U.S. National Weather Service 1997) average rainfall in Prince William Sound is much greater (e.g., about 25 cm in August at 3 sites) than in the Gulf of Alaska (10 cm at 4 sites) or Aleutian islands (11 cm at 3 sites), where the bulk of Alaskan Tufted Puffin colonies are located. In an analysis of seabird breeding colonies with respect to climate, Kaiser and Forbes (1992) concluded that burrow-nesting seabirds select colony-sites with minimal rainfall. They noted that drier nesting sites offer several advantages, including reduced burrow erosion, low risk of flooding, and easier maintenance of burrow microclimate. Heavy rainfall during chick-rearing can seriously reduce chick survival, because wet chicks may die of hypothermia (Piatt et al. 1990, Kaiser and Forbes 1992).

In summary, Tufted Puffin colonies in Prince William Sound are relatively small compared to those found just outside the Sound (for example, the Chiswell Islands), and elsewhere in the Gulf of Alaska. Forage fish densities in Prince William Sound during 1995 were apparently sufficient to support the existing Tufted Puffin colonies, but population growth may ultimately be limited by low prey densities. Populations may be limited also by a lack of suitable nesting habitat, and by the heavy rainfall in Prince William Sound.
Acknowledgments

Funding for this project was provided by the Exxon Valdez Oil Spill Trustee Council and the Biological Resources Division, USGS. We thank Thomas van Pelt and Ann Harding for help with logistics, and Marc Romano for assistance in preparing the manuscript. We thank Vernon Byrd and two anonymous reviewers for comments on earlier drafts of the paper.
